# 1: Demonstration of Stereo Mapping Technology

## 1.1 Introduction

The focus of the research over this postdoctoral contract has been in augmenting and refining the specification of image matching strategies to be employed in an advanced stereo mapping system. Initially, our research task was to evaluate a preliminary design for a mapping system, and then by carrying out test implementations of elements of this proposed system, to iterate on the design process. As part of a continuing mapping program, this phase of the research would lead to more effective representations and improved matching strategies for surface reconstruction. The test implementations would build to provide a foundation on which we would develop an experimental rule-based stereo matching system. As part of this experimental system, we undertook to develop an interactive test facility to provide hand synthesized data for rule analysis. A change in the scope of the project occurred shortly after we had begun the research, and necessitated a redirection in the emphasis; rather than evaluating or continuing the design, we were to:

- a) experiment with an existing matching system (showing its capabilities and assessing its applicability to the planned system);
- b) demonstrate the design and the utility of the rule-based approach to surface inference from monocular information;
- c) develop tools to support an interactive test facility.

## 1.2 Scope of the Research

In a), we undertook to apply an existing stereo mapping system [Baker 1981] to some new imagery. This was designed to demonstrate its effectiveness, to expose its limitations, and to suggest both its role in an advanced mapping system and complementary research needed to improve its utility. Significant restructuring of the system was called for in enabling it to process this imagery. Details of these changes are described in section 5, which deals with the matching process. The modifications have now been implemented, enabling the system to:

- function on the output of an improved edge operator [Marimont 1982];
- use edge extent as one of its parameters in seeking optimized correspondence;
- exploit prepared transform information in processing images whose epipolar lines are not collinear with the scanning axes of the cameras.

Separate funding sources supported research in analysis and synthesis of rules for inference of three-dimensional shape from single images. This inference also has application in constraining search for matches in stereo correspondence. We will describe here some results of this research,

and, as part of the demonstration, will show its use in shape inference and search constraint in the domain of Orthogonal Trihedral Vertices (OTV's).

Our work in developing tools has centered on:

- a) a system for the hand construction of edge descriptions from hard copy imagery;
- b) an interactive system for determining the transform to bring image pairs into collinear epipolar registration.

Both of these systems make extensive use of interactive graphics, and the latter takes much advantage of previous stereo research from our laboratory ([Gennery 1980]).

These are the three principal areas to be covered in this report:

- experimentation with the automated mapping system;
- assessment of rule synthesis from manual and automated edge processes;
- development of test facility tools for edge extraction and image registration.

### 1.3 Specific Tasks

We will describe results in these areas of the research through discussion of the following:

- a) implementation of the digitizing test facility;
- b) the use of image edge descriptions produced using this facility and from an automated process [Marimont 1982] in synthesizing rules for stereo matching;
- c) examination of Orthogonal Trihedral Vertex (OTV) inference rules;
- d) development of a system for registration of image pairs;
- e) analysis of stereo imagery with an automated stereo process.

## 2: Digitizing Facility

### 2.1 Background

Our approach to rule development begins with hand synthesized and some automatically generated edge data. We have systems for the automatic generation of edge data (*i.e.* [Marimont 1982]). This data, extracted from a sufficiently wide selection of imagery types, gives good insight into the current capabilities of automated processes. Automated processes, however, are not able presently to give as meaningful a description of an image as we would like, and have not been designed to provide the aggregated abstractions research systems ([Lowe 1982]) will be soon supplying. To bridge this inadequacy, we work with both automatically generated data (the current state-of-the-art), and hand generated data (representative of the next generation of edge analysis processes). The hand generated data is obtained from a manually operated digitizing tablet. We have written a graphics-based digitizing and editing system to run with a GTCO tablet in producing these image descriptions. Section 6 lists instructions for the use of this program with the bitpad (GTCO tablet), and section 9 contains a source listing of the program.

### 2.2 Imagery Analysis with the Tablet

Figure 2-1 below shows an image pair of a building complex (referred to as the Sacramento imagery). Figure 2-2 shows the results of bitpad edge extraction on these images. Figure 2-3 shows the results of the Marimont operator [Marimont 1982] on the image pair. Manually generated edge data was produced using this facility for the analysis of rule synthesis of section 3. It was also used to digitize the building data of figures 2-1 for input to the OTV inference process, as figure 3-1.

### 3: Inference and Modelling

#### 3.1 Introduction

We have been addressing inference of matching rules and the use of model-based analysis both with theoretical analyses and with hand and automated analyses of specific matching strategies; the latter applied to both real and synthesized imagery examples.

We have obtained extended edge data from hand and automated processing for use in synthesis of matching rules. Results from earlier work on OTV analysis (orthogonal transform vertices) have been exploited, and a demonstration of the use of such a rule for shape inference and in constraining search for correspondence has been prepared. Other funding has supported research in representation of generic structures. We have taken examples from this model-based research to produce ground and aerial views of a building complex, and have used this, as well as other data, in rule synthesis.

#### 3.2 Geometric Modelling and Computer Vision

##### 3.2.1 – Modelling, prediction and interpretation

Of course, one of the primary goals of research in computer vision is the development of systems that can recognize and locate objects in images. In order to identify such an object, it is clearly necessary to have some description of its characteristics that can be detected in an image. A *representation* of an object is the form this description takes.

One approach to representation is to provide the system with three-dimensional models of objects. Rotation of these models will allow objects to be observed, conceptually, from differing viewpoints. If parameters in a particular model are allowed to vary it is possible to have that single model represent a whole class of objects; constraining the parameters functions to delimit sub-classes. Further model manipulations, such as partitioning and projection, can be used to aid in mapping model to imagery data. The information contained in such object models may be used to determine possible interpretations of image features (*e.g.*, edges, ribbons, corners) and to provide feedback to predict the locations of such features in an image.

ACRONYM [Brooks 1981] is a three-dimensional rule-based modelling/vision system developed here at Stanford that provides, among other things, such feature prediction, model manipulation, and image interpretation. The rule-base operates on the models and on the sensed data to accomplish scene interpretation. Such a rule-based approach has been shown to be an effective form for constraint and search implementation, and allows easy modification and addition of new rules without the need of altering the underlying code.

Our group's intention over the next few years is to build a rule-based stereo system operating within ACRONYM whose functioning will include model-based prediction. Working toward this,

we have been carrying out experiments on scene inference and model-based prediction that will lead to a repertoire of stereo matching rules.

### **3.2.2 – Models and stereo matching**

One of the major difficulties in determining stereo correspondence is in dealing with the large number of matches that are possible. Solution is generally found by search through a large parameter space, where possible correspondences are limited by geometric or photometric constraints. Search can be reduced even more dramatically by endowing the matcher with broad domain specific and domain independent knowledge. Such knowledge can be rule-based and model-based. Our proposition here is that the three-dimensional information in object models, along with inference and prediction mechanisms, can be used to interpret features in image pairs. These interpretations can then be used as filters to constrain the matching. We demonstrate this notion with the example of Orthogonal Trihedral Vertices, often referred to as cube corners or OTVs. Other rules synthesized from analysis of both manually extracted and automated edge processes follow.

The work on cube corners points to additional usefulness for a model-based approach. OTV orientation analysis (from matches across pairs of views) yields almost complete solution for camera parameters; constraints on sizes (again, from rules and models) could complete the camera solution. But the orientation information yielded by a match of a pair of vertices is valid only if the vertex is a cube corner; thus it is necessary to be able to distinguish between vertices that are cube corners and those that are not. If the models contain sufficient information to identify cube corners, then the problem of determining cube corners independently of the identification process is eliminated. In fact, both the search for cube corners and the search for identification are likely to be reduced when they are combined.

### **3.2.3 – OTV rule-based analysis**

#### **OTV theory**

In cultural scenes, we find a large number of interior and exterior corners of cubes – typically when two walls at right angles meet the roof or the floor. The importance of utilizing this common structural element – the Orthogonal Trihedral Vertex (OTV) – has been emphasized earlier [Liebes 1981]. Since they provide a very tight constraint – the three edges are mutually orthogonal in space – it is possible to calculate the three dimensional orientations given the projections in the image. This can be done for both orthographic and perspective viewing.

If the eye is assumed to be focussed on the vertex of the cube corner, perspective can be ignored and the projection of a cube corner in  $XYZ$  space will simply be its orthogonal projection on the  $XY$  plane. Suppose that some 3 - star has angles between its rays  $a$ ,  $b$  and  $c$  and also that the rays are represented by the unit vectors  $v_1$ ,  $v_2$ ,  $v_3$ . We are interested in detecting whether there

are three vectors in  $XYZ$  space, which are mutually orthogonal and project, respectively to  $v_1$ ,  $v_2$ ,  $v_3$ .

Since projection is accomplished by dropping the  $z$ -component, any 3 such vectors must be of the form  $v_1 + \lambda_1 z$ ,  $v_2 + \lambda_2 z$ , and  $v_3 + \lambda_3 z$  where  $z$  is the unit vector in the  $z$ -direction.

Requiring mutual orthogonality implies that the dot products of these vectors in pairs be zero. From these conditions and some simple manipulations we can calculate the formulas for

$$\lambda_1 = \pm \sqrt{-\frac{(\cos a)(\cos c)}{(\cos b)}}, \quad \lambda_2 = \pm \sqrt{-\frac{(\cos a)(\cos b)}{(\cos c)}}, \quad \lambda_3 = \pm \sqrt{-\frac{(\cos c)(\cos b)}{(\cos a)}}$$

Hence solutions exist if

- a)  $\cos a$ ,  $\cos b$ ,  $\cos c$  are all non-zero and
- b) either one or three of  $\cos a$ ,  $\cos b$ ,  $\cos c$  are negative, so that the quantities under the square root sign are positive.

These results were first derived in [Perkins 1968].

Thus we have a way of both eliminating false candidates for being OTVs and finding the 3-D orientations of valid OTV's. This algorithm has been implemented and run on data from the digitizing tablet.

#### OTV with/from models

Our analysis begins on both images, processing bottom up on the two images separately. As the rule system identifies likely OTVs in images (from its models), it proceeds to match them. The system should already have a tentative identification of the buildings containing the OTVs, so there should be relatively few possible matches at this point. Only OTVs that could be the same point on the same object need be compared. The analysis results in depths of matched objects, for all those objects having OTVs.

This requires that the modelling system handle point elements, and that it include both:

- inferring OTVs from models (volumes);
- accessing OTVs stored explicitly with the models.

### 3.3 Rule Synthesis

#### 3.3.1 - Inference rules

We continue with the development of inference rules. This work is a logical extension of previous work [Binford 1981, Lowe 1982] done at Stanford in developing rules for inferring surface information from a single view. General assumptions about illumination, object geometry, the imaging process etc. have been used to derive rules for making specific inferences. For stereo vision Arnold and Binford [Arnold 1980] have developed conditions on correspondence of edge and surface intervals. We divide our rules into two categories: monocular rules, which enable surface inference from a single view; and stereo rules, which facilitate cross-image matching.

#### 3.3.2 - Monocular and stereo rules.

1. Monocular rules - Rules which have been developed for inferences from monocular views can be utilised to provide a partial 3-dimensional interpretation which directs search in the second view. This category includes the rule for interpretation of Orthogonal Trihedral Vertices.

Another example is the T-junction rule [Binford 1981] which states that *'In absence of evidence to the contrary, the stem of a T is not nearer than the top, i.e. is coincident in space or further away'*. Application of this rule gives a set of nearer/farther relations. A hypothesized correspondence of edges which leads to inconsistent conclusions from the two views can be pruned from the search.

An image line which is straight must be the image of a straight space curve unless the curve is planar and the observer is coincidentally aligned with the plane of curvature. This enables us to dismiss correspondences between straight edges in one view and curves in the other view. If two image curves are projectively consistent with parallel, we assume they are images of curves which are parallel in space. That implies that their images in the other view would be parallel i.e. parallels map to parallels.

As these examples illustrate, most of the rules in [Binford 1981, Lowe 1982] and others developed by Malik and Binford have as direct corollaries stereo rules for checking the legality of a match. They can even direct the search process.

2. Stereo Rules – these are rules which have been derived from the stereo imaging process, and are a function of the imaging geometry.

An example rule in this class, which has long been used for finding stereo correspondences, is the epipolars rule – corresponding points must lie on corresponding epipolar lines. These rules have inherently no monocular analogs. Here are a few:

- a) Horizontal planes in one view get mapped to horizontal planes in the other view.
- b) Use of projective and quasi-projective invariants. This has not been examined in detail. Duda and Hart[Duda 1973] devote a chapter to this topic which has not really been exploited in stereo work.
- c) Conditions on correspondence of edges and surface intervals[Arnold 1980].
- d) Surface Occlusion rules:

Surfaces visible in one view can be occluded in the other view. We are interested in the conditions when this takes place. The basic idea is that if we cross a surface, an obscuration of edge occurs. A left surface visible in a right view is visible in the left view unless there is obscuration by a tall object. Similarly a right surface visible in a left view will be seen unless obscured by a tall object. These surface-obscuration rules can be formalized by the cross-product rule:

For the hypothesized edge match  $e_1$  with  $f_1$  and  $e_2$  with  $f_2$ , we compute the Z-component of the vector cross-product in the left image pair and the right image pair. If the z-components have opposite signs, we are seeing opposite sides of the surface. That implies that the object is not opaque.

### 3.3.3 - Use of inference rules in a test analysis

Our preliminary results indicate good potential for the success of this approach. On hand simulations with line drawings of stereo pairs, the rules helped narrow down the choices considerably.

Consider the imagery shown in figures 3-1 and 3-2. Figure 3-1 is the right view and 3-2 the left view. Vertices 1, 2, 3 are orthogonal trihedral vertices. Using the formulae developed earlier, we can find the 3-D orientations of the edge vectors. These can be matched with the 3-D orientations of  $1'$ ,  $2'$ ,  $3'$  to obtain a registering of these vertices when combined with the epipolar constraint. All OTV's in one view need not be visible in the other i.e.  $4'$ . Of the monocular constraints, the other major constraints which can be seen here are the T-junction rule and the parallels rule. In figure 3-2 edge 5 is behind edge 6. Edges 7 and 8 are parallel and so are  $7'$  and  $8'$ . A match of 8 with  $9'$  would not be accepted. Surfaces  $S_1$  and  $S_2$  are both horizontal planes (as can be deduced from the OTV analysis) and can be matched. Surface  $S_3$  is not horizontal. Here of course, this does not provide any new information. Surface  $S_4$  being a left face in a left view is not guaranteed to be visible in the other view - as in fact it is. The cross-product rule could be used to dismiss a match between 10 and  $10'$ .

## 4: Image Registration

### 4.1 Introduction to Epipolar Geometry

The search process in automated stereo mapping can be greatly restricted, and computation times significantly reduced, if information is available relating the relative camera geometries of a stereo pair. Often this information is available in the reconnaissance data (or at least a rough approximation to it). Other manual and automated schemes have been devised to provide the information when it is not present with the imagery ([Gennery 1980], [Hallert 1960]). This camera geometry information allows establishing epipolar correspondence of lines across images. When this has been done, search in one image for match points of a feature in the other image can be constrained along a single vector. More generally, any features lying along a particular vector in the one image may be found along a single vector in the other image. These image plane vectors are termed epipolar lines. Corresponding vectors are termed corresponding or conjugate epipolar lines.

In this section we detail an algorithm for determining conjugate epipolar lines in a set of imagery for which such camera geometry information is not explicitly available. Here, we rely upon an operator to select corresponding points in the two images. The system automatically improves the resolution of the correspondence through Fourier interpolation over a match window [Gennery 1980]. The set of such points is taken by an automated camera solver to produce the needed geometric information. This point selection is done with pan/zoom cursor control on a graphics device. If the camera information is available (as, for example, from reconnaissance data), then the point matching phase may be omitted (although this provision has not been enabled in the current system). Equally, rough camera geometry information, if available, may be used to partially automate the point selection phase, although again this is not implemented here. [Gennery 1980] and [Moravec 1980] have implemented totally automatic camera solvers in their stereo matching systems. Our next improvement to this system will be to incorporate the image sampling and feature matching of the [Gennery 1980] system, removing the need for manual point selection.

## 4.2 Glossary of Terms

Given two cameras  $C_1$  and  $C_2$  with origins  $\theta_1$  and  $\theta_2$  and focal planes  $P_1$  and  $P_2$ , we call:

**Bundle of lines:** A family of lines containing a common point.

**Epipolar coordinates of a point:** The number of the epipolar line it belongs to, and its distance to a fixed reference, like the epipole if it exists.

**Epipolar direction:** The direction of all epipolar lines if they are parallel.

**Epipolar line:** The intersection of an epipolar plane with a focal plane. Alternate definition: the image in one camera of the pre-image of a point in the other camera's focal plane.

**Epipolar plane:** Any plane containing the two camera centers  $\theta_1$  and  $\theta_2$ .

**Epipolar space:** A space where the coordinates are the epipolar coordinates. In this space, a horizontal line is an epipolar line, and the epipole, if it exists, is a whole vertical line.

**Epipole:** The intersection, if it exists, of all epipolar lines in a focal plane.

**Conjugate epipolar lines:** the intersections of an epipolar plane with the two focal planes.

Epipolar Geometry  
Figure 4-1

### 4.3 Background Theory

Given two stereo images  $P_1$  and  $P_2$  (the content of the focal planes  $P_1$  and  $P_2$  of the cameras), and two lines  $L_1$  and  $L_2$  contained in  $P_1$  and  $P_2$ , in general every point of  $L_1$  maps to a line segment in  $P_2$ , and there is no particular relationship between the line segments mapping to different points.

#### Fundamental property:

Every point in  $L_1$  will map to a line segment contained in the same line  $L_2$  if and only if  $L_1$  and  $L_2$  are a pair of conjugate epipolar lines.

#### Epipolar Geometry:

The family of epipolar lines in a focal plane is:

Either

- a) a set of parallel lines having a common epipolar direction,

or

- b) a bundle of lines, the intersection of which is the epipole.

### 4.4 Requirements of the System

Given a pair of stereo images, we want to:

- 1) identify the kind of epipolar geometry present in the images;
- 2) explicitly show the epipolar lines belonging to each image;
- 3) for each image, compute the parameters which relate the original coordinates to the epipolar coordinates;
- 4) construct the image transforms in epipolar space.

Prior to these 4 steps, we will need to solve for the cameras, that is, to determine the 5 parameters describing their relative orientation. A procedure developed at Stanford [Gennery 1980] is used for this. We proceed as above, using simple analytic geometry for our calculations.

### 4.5 Algorithm Used

#### 4.5.1 - Camera registration output

Each camera is viewed as a referential  $(\theta_i, x, y, z)$ ,  $i \in \{1, 2\}$ . The registration procedure yields *azimuth*, *elevation*, *pan*, *tilt*, and *roll* of one camera with respect to the other. From there, we compute:

Top view of a situation with only one epipole  
Figure 4-2

(When  $M$  takes all possible values in space,  $E_1$  and  $E_2$  still belong to the intersection of  $O_1, O_2, M$  with  $P_1$  and  $P_2$ )

Top view of a situation with epipoles  
Figure 4-3

- 1) the rotation matrix  $R$  between the two referentials:

$$R = \begin{pmatrix} r_{11} & r_{12} & r_{13} \\ r_{21} & r_{22} & r_{23} \\ r_{31} & r_{32} & r_{33} \end{pmatrix}$$

- 2) the translation unit vector  $t$ , the components of which are:

$$\begin{pmatrix} \alpha \\ \beta \\ \gamma \end{pmatrix} \text{ in the base } \theta_1xyz, \quad \begin{pmatrix} \lambda \\ \mu \\ \nu \end{pmatrix} \text{ in the base } \theta_2xyz$$

Note that the magnitude of the translation vector cannot be determined from a pair of images.

#### 4.5.2 - Epipolar geometry determination

The focal planes  $P_i$  are planes parallel to  $\theta_i xy$ , intersecting  $\theta_i z$  at  $z = f_i$ , the focal distance. There is an epipole in plane  $P_i$  if and only if the translation vector intersects this plane, that is, if and only if its third component is not zero.

We thus determine the case we are working with:

- if  $\gamma \neq 0$  and  $\nu \neq 0$ , there are two epipoles: CASE 1
- if  $\gamma \neq 0$  and  $\nu = 0$ , there is one epipole  $E_1$ : CASE 2
- if  $\gamma = 0$  and  $\nu \neq 0$ , there is one epipole  $E_2$ : CASE 3
- if  $\gamma = 0$  and  $\nu = 0$ , there are no epipoles: CASE 4

#### Remarks:

- a)  $\gamma = 0$  is replaced in the code by  $|\gamma| < \text{threshold}$ , where threshold is chosen as a function of the arithmetic precision of the machine: if we had infinite precision, then we could consider every case as being case 1. Here threshold = .0001 was found to be a good estimate.
- b) Most image pairs will belong to the first case, with  $\gamma$  and  $\nu$  of the order of .1. The epipoles exist, are outside the picture frame, and, for the images worked with to date, tend to be at a distance of about 10 times the picture dimension.

### 4.5.3 – Epipoles and epipolar directions

If the epipole  $E_i$  exists, it is the extremity of the vector collinear to the translation vector, with a third component equal to  $f_i$ . If it does not, then the translation vector is the epipolar direction. Hence:

$$\text{Case 1: } E_1\left(\frac{\alpha f_1}{\gamma}, \frac{\beta f_1}{\gamma}\right) \quad E_2\left(\frac{\lambda f_1}{\nu}, \frac{\mu f_1}{\nu}\right)$$

$$\text{Case 2: } E_1\left(\frac{\alpha f_1}{\gamma}, \frac{\beta f_1}{\gamma}\right) \quad V_2(\lambda, \mu)$$

$$\text{Case 3: } V_1(\alpha, \beta) \quad E_2\left(\frac{\lambda f_2}{\nu}, \frac{\mu f_2}{\nu}\right)$$

$$\text{Case 4: } V_1(\alpha, \beta) \quad V_2(\lambda, \mu)$$

### 4.5.4 – Epipolar line calculation

#### 4.5.5 – CASE 1: two epipoles

##### a) theory

Let  $M_1(x_1, y_1, z_1)$  be a point in  $P_1$ .  $E_1M_1$  defines an epipolar line in  $P_1$ , and the corresponding  $E_2M_2$  defines the conjugate epipolar line in  $P_2$ . The plane  $(E_1, \theta_1, \theta_2, E_2, M_1, M_2)$  contains the translation vector  $t$  and  $E_1M_1$ . Its normal is  $E_1M_1 \times t$ . The normal of  $P_2$  is  $\theta_2z$ . Hence the intersection of the two planes is given by the vector:

$$\theta_2z \times (E_1M_1 \times t) = (\theta_2z \cdot t)E_1M_1 - (\theta_2z \cdot E_1M_1)t$$

and  $E_2M_2$  is collinear to this vector. Suppose that in  $\theta_1xyz$ ,  $E_1M_1: (x_1, y_1, 0)$ . In terms of components in  $\theta_2xyz$ :

$$\theta_2z = \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix}, \quad t = \begin{pmatrix} \lambda \\ \mu \\ \nu \end{pmatrix}, \quad E_1M_1 = \begin{pmatrix} x'_1 \\ y'_1 \\ z'_1 \end{pmatrix} = \begin{pmatrix} r_{11}x_1 + r_{12}y_1 \\ r_{21}x_1 + r_{22}y_1 \\ r_{31}x_1 + r_{32}y_1 \end{pmatrix}$$

$$E_2M_2 \text{ is collinear to } \begin{pmatrix} \nu x'_1 - \lambda z'_1 \\ \nu y'_1 - \mu z'_1 \end{pmatrix} = \begin{pmatrix} x_1(\nu r_{11} - \lambda r_{31}) + y_1(\nu r_{12} - \lambda r_{32}) \\ x_1(\nu r_{21} - \mu r_{31}) + y_1(\nu r_{22} - \mu r_{32}) \end{pmatrix}$$

If we let  $A$  be the matrix:

$$\begin{pmatrix} \nu r_{11} - \lambda r_{31} & \nu r_{12} - \lambda r_{32} \\ \nu r_{21} - \mu r_{31} & \nu r_{22} - \mu r_{32} \end{pmatrix}$$

Then we can write  $E_2 M_2 = A E_1 M_1$  where  $E_1 M_1$  is in base  $\theta_1 xy$  and  $E_2 M_2$  is in base  $\theta_2 xy$ .

Case 1  
Figure 4-4

**b) algorithm**

Let  $N_1$  be the number of epipolar lines that we want to determine. Each epipolar line is uniquely determined by the angle it makes with the  $x$ -axis. Let  $\theta$  be this angle. Given  $k$ , the epipolar line number,  $0 \leq k \leq n_1 - 1$ , how can we determine  $\theta$ ? If  $\theta_0$  and  $\theta_1$  are the lower and upper limits between which  $\theta$  is allowed to vary, and  $\theta_2 = \frac{(\theta_1 - \theta_0)}{N_1}$ , then we will choose the middle of each interval:  $\theta = \theta_0 + (k + .5)\theta_2$ . But what are  $\theta_0$  and  $\theta_1$ ? We have to distinguish between three cases:

- The epipole is in the picture (very unlikely). Then  $\theta$  can vary between 0 and  $2\pi$  radians;

- The epipole is outside the image: there is a minimum and maximum angle under which the image is seen from this point. If we choose these angles in  $[0, 2\pi]$ , then most of the time every  $\theta \in [\theta_0, \theta_1]$  will define a valid epipolar line in  $P_1$ ;
- The exception from above is when the epipole is left of the image but on a same vertical level: then  $[\theta_0, \theta_1]$  cannot be connected and still included in  $[0, 2\pi]$ . In this case we will choose the angles in  $[-\frac{\pi}{2}, \frac{\pi}{2}]$ .

Then  $L_1$  will be defined by the point  $E_1$  and the vector  $V_1(\cos\theta, \sin\theta)$ , and  $L_2$  is defined by  $E_2$  and  $V_2 = AV_1$ .

#### 4.5.6 – CASE 2: one epipole $E_1$

##### a) theory

Given an epipolar line  $\frac{L_1}{E_1 M_1}$ , we already know that the corresponding epipolar line  $L_2$  in  $P_2$  is collinear to the vector  $t = V_2(\lambda, \mu)$ . Hence we just need to find a point belonging to  $L_2$ . Clearly,  $L_2$  is the intersection of  $P_2$  with the plane  $(E_1, M_1, \theta_2)$ . Thus any line contained in this plane will intersect  $P_2$  at a point contained in  $L_2$ . In particular, consider the parallel to  $L_1$  driven through  $\theta_2$ . It intersects  $P_2$ , thus  $L_2$ , at  $M_3$  such that, in base  $\theta_2xyz$ :

$$E_1 M_1 = \begin{pmatrix} r_{11}x_1 + r_{12}y_1 \\ r_{21}x_1 + r_{22}y_1 \\ r_{31}x_1 + r_{32}y_1 \end{pmatrix}, \quad \text{hence} \quad \theta_2 M_3 = \begin{pmatrix} f_2 \frac{(r_{11}x_1 + r_{12}y_1)}{r_{31}x_1 + r_{32}y_1} \\ f_2 \frac{(r_{21}x_1 + r_{22}y_1)}{r_{31}x_1 + r_{32}y_1} \\ f_2 \end{pmatrix}$$

##### b) algorithm

In the same way as in case 1, we define  $L_1(E_1, V_1)$  where  $V_1(x_1 = \cos\theta_1, x_2 = \sin\theta_2)$ . Then  $L_2$  is defined by  $(M_3, V_2)$ , where the coordinates of  $M_3$  are

$$\left( f_2 \frac{r_{11}x_1 + r_{12}y_1}{r_{31}x_1 + r_{32}y_1}, f_2 \frac{r_{21}x_1 + r_{22}y_1}{r_{31}x_1 + r_{32}y_1} \right)$$

Case 2  
Figure 4-5

#### 4.5.7 - CASE 3: one epipole $E_2$

##### a) theory

Let an epipolar line in  $P_1$  be defined by the translation vector  $t = V_1$  and by a point  $M_1$  we pick. In  $P_2$ ,  $L_2$  goes through  $E_2$  and is collinear to a vector  $E_2M_2$ , intersection of  $P_2$  with the plane  $(\theta_2, E_2, M_1)$ . This plane is orthogonal to  $\theta_2 M_1 \times t$  and  $P_2$  is orthogonal to  $\theta_2 z$ . Hence the intersection is collinear to  $\theta_2 z \times (\theta_2 M_1 \times t)$

$$\begin{aligned} \text{since } \theta_2 M_1 &= \theta_2 \theta_1 + \theta_1 M_1 \\ &= kt + \theta_1 M_1, \end{aligned}$$

$$\theta_2 M_1 \times t = \theta_1 M_1 \times t,$$

$$\text{and } \theta_2 z \times (\theta_2 M_1 \times t) = (\theta_2 z \cdot t) \theta_1 M_1 - (\theta_2 z \cdot \theta_1 M_1) t.$$

Suppose  $\theta_1 M_1 : (x_1, y_1, f_1)$  in  $\theta_1 xyz$ . Then in  $\theta_2 xyz$ :

$$\theta_2 z = \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix}, \quad t = \begin{pmatrix} \lambda \\ \mu \\ \nu \end{pmatrix}, \quad \theta_1 M_1 = \begin{pmatrix} x'_1 \\ y'_1 \\ z'_1 \end{pmatrix} = \begin{pmatrix} r_{11}x_1 + r_{12}y_1 + r_{13}f_1 \\ r_{21}x_1 + r_{22}y_1 + r_{23}f_1 \\ r_{31}x_1 + r_{32}y_1 + r_{33}f_1 \end{pmatrix}$$

$E_2 M_2$  is thus collinear to:

$$\begin{pmatrix} \nu x'_1 - \lambda z'_1 \\ \nu y'_1 - \mu z'_1 \end{pmatrix} = \begin{pmatrix} x_1(\nu r_{11} - \lambda r_{31}) + y_1(\nu r_{12} - \lambda r_{32}) + f_1(\nu r_{13} - \lambda r_{33}) \\ x_1(\nu r_{21} - \mu r_{31}) + y_1(\nu r_{22} - \mu r_{32}) + f_1(\nu r_{23} - \mu r_{33}) \end{pmatrix}$$

Hence, if we let  $A$  be the same matrix as in CASE 1 and OF3 be the offset matrix:

$$\begin{pmatrix} \nu r_{13} - \lambda r_{33} \\ \nu r_{23} - \mu r_{33} \end{pmatrix}$$

Then we have:  $E_2 M_2 = A \theta_1 M_1 + OF3$

Where  $\theta_1 M_1$  is in base  $\theta_1 xy$  and  $E_2 M_2$  is in base  $\theta_2 xy$

#### b) algorithm

Now, how do we pick  $M_1$  in the first place? We want a set of  $N_1$  equally spaced epipolar lines, and it appears convenient to pick points on the axes. If the epipolar lines are more horizontal, or the image stretched in height, then we will pick  $N_1$  equally spaced points on the vertical axis, suitably located to cover the entire image. If the epipolar lines are more vertical or the image more stretched in width, then we pick them on the horizontal axis. Let  $L_x, L_y$  be the picture dimensions and  $(V_x, V_y)$  the epipolar direction:

If  $V_x L_y < V_y L_x$ , and  $V_y < 0$ , we pick  $y_1 = (L_x | \frac{V_y}{V_x} | + L_y) (\frac{K+0.5}{N_1})$

If  $V_x L_y < V_y L_x$ , and  $V_y > 0$ , we pick  $y_1 = (L_x | \frac{V_y}{V_x} | + L_y) (\frac{K+0.5}{N_1}) - L_x \frac{V_y}{V_x}$

If  $V_y L_x < V_x L_y$ , and  $V_y < 0$ , we pick  $x_1 = (L_y | \frac{V_x}{V_y} | + L_x) (\frac{K+0.5}{N_1})$

If  $V_y L_x < V_x L_y$ , and  $V_y > 0$ , we pick  $x_1 = (L_y | \frac{V_x}{V_y} | + L_x) (\frac{K+0.5}{N_1}) - L_y \frac{V_x}{V_y}$

Then we proceed as indicated above:

$$L_1(M_1, V_1 = t) \text{ is matched with } L_2(E_2, V_2 = F_2 M_2).$$

**4.5.8 - CASE 4: no epipoles****a) theory**

Let an epipolar line in  $P_1$  be defined by the translation vector  $t = V_1$  and by a point  $M_1$  we pick. In  $P_2$ ,  $L_2$  goes through the image of  $M_1$ , that is the extremity of a vector collinear to  $\theta_1 M_1$  and whose third component is  $f_2$ . In base  $\theta_1 xyz$ ,  $\theta_1 M_1 : (x_1, y_1, f_1)$ . In base  $\theta_2 xyz$ :

$$\theta_1 M_1 = \begin{pmatrix} r_{11}x_1 + r_{12}y_1 + r_{13}f_1 \\ r_{21}x_1 + r_{22}y_1 + r_{23}f_1 \\ r_{31}x_1 + r_{32}y_1 + r_{33}f_1 \end{pmatrix} \quad \theta_2 M_2 = \begin{pmatrix} f_2 \frac{r_{11}x_1 + r_{12}y_1 + r_{13}f_1}{r_{31}x_1 + r_{32}y_1 + r_{33}f_1} \\ f_2 \frac{r_{21}x_1 + r_{22}y_1 + r_{23}f_1}{r_{31}x_1 + r_{32}y_1 + r_{33}f_1} \\ f_2 \end{pmatrix}$$

**b) algorithm**

We pick points  $E_1$  in the same manner as in case 3. Then we calculate  $\theta_2 M_2$  as indicated above and we match  $L_1(E_1, t)$  with  $L_2(E_2, t)$ .

**4.6 Transform Parameters**

We want to output the minimum necessary parameters to do the following transformation:

given the coordinates of one point in one image, find its coordinates in epipolar space.

We treat the problem only in CASE 1, which is the most common case encountered. For this case, we will need:

- the coordinates of the epipoles;
- the number of epipolar lines;
- the minimum and maximum angle  $\theta_0$  and  $\theta_1$  under which picture 1 is viewed;
- the minimum distances  $D_{1min}$  and  $D_{2min}$  of the epipoles to the images;
- the matrix  $R$ , or rather its inverse  $R^{-1}$ .

For example, the images of figure 5-6 have transform parameters as follows:

*Case = 1*

$$N = 450$$

$$E_{11} = 358755.3$$

$$E_{12} = 186509.8$$

$$E_{21} = -7765.348$$

$$E_{22} = -3509.268$$

$$\theta_0 = 3.578705$$

$$\theta_1 = 3.577792$$

$$D_{1min} = 393249.0$$

$$D_{2min} = 8521.478$$

$$R_{11}^{-1} = 430.7463$$

$$R_{12}^{-1} = 2375.517$$

$$R_{21}^{-1} = 215.9756$$

$$R_{22}^{-1} = 1075.811$$

#### 4.7 Example of Epipolar Registration and Transformation

Figure 4-6 shows a stereo pair of a building complex. Figure 4-7 has this pair superpositioned with a set of corresponding epipolar lines. Figure 4-8 shows the imagery transformed such that epipolar lines are horizontal in the image, and conjugate epipolar lines have the same row coordinate.

## 5: Analysis of Automated Stereo Mapping

### 5.1 Background

Results from our laboratory over the past few years [Quam 1971, Hannah 1974, Moravec 1980, Gennery 1980, Arnold 1980, Baker 1981, Arnold 1983], have demonstrated the possibilities of both area-based and feature-based stereo matching.

*Area-based* stereo matching uses windowing mechanisms to isolate parts of two images for cross-correlation. *Feature-based* stereo matching uses two-dimensional convolution operators (and perhaps grouping operators) to reduce an image to a depiction of its intensity boundaries, which can then be put into correspondence. Area-based cross-correlation techniques require distinctive texture within the area of correlation for successful operation. They break track:

- where there are ambiguous textures or featureless areas (roofs, sand and concrete);
- where the correlation area crosses surface discontinuities (at occlusions such as buildings, or thin objects (poles));
- where depth is ill-defined (such as through trees).

In general, these systems break track where there is no local correlation (zero signal, or where two images do not correspond) or where the correlation is ambiguous (where the signal is repetitive). The systems must be started manually and corrected when they break track.

Demands of mapping in cultural sites and in locales with surface discontinuity and ambiguous or non-existent texture make it essential that, if area-based analysis is to be done, it be done in conjunction with feature-based analysis. *Feature-based* analysis provides a solution to many of the problems of correlation. Principal among its advantages is that it operates on the most discriminable parts of an image: places that are distinctive in their intensity variation, and where localization is greatest. These are typically the boundaries between objects or between details on objects, or between objects and their backgrounds. The important point is that the features being put into correspondence for depth estimates are the boundaries of objects: area-based analysis is at its worst at object boundaries, yet determining boundaries can be said to be the most important part of mapping in 3-space.

Some other advantages of feature-based analysis are:

- a) *reduced combinatorics* — there are fewer features than pixels,
- b) *greater accuracy* — features can, in general, be positioned to sub-pixel precision, while area positioning precision is inversely proportional to window size, and considerably poorer, and
- c) *more realistic invariance assumptions* — area-based analysis presupposes that the *photometric* properties of a scene are invariant to viewing position, while feature-based analysis works with the assumption that it is the *geometric* properties that are invariant to viewing position.

The Baker system [Baker 1981] is the only current system that mixes these two matching modalities. We undertook in this postdoctoral work to demonstrate the capabilities of this system applied to new cultural imagery.

### 5.2 Baker System: before

In the Baker system, image *edges* are the features considered in stereo matching. These edges are located at positions in the image where a change in sign of second difference in intensity occurs. In the initial case a particular operator (one that was 1 by 7 pixels in size) measured the directional first difference in intensity at each pixel. Second differences were computed from these, and changes in sign of these second differences were used to interpolate zero crossings (i.e. peaks in first difference). Certain local properties other than *position* were measured and associated with each edge — *contrast*, *orientation*, and *intensity to either side* — and *links* were kept to nearest neighbors above, below, and to the sides. It is these properties that define an edge and provide the basis for the correspondence process.

The correspondence is a search for *edge* matches across images. With no prior knowledge of the viewing situation, one could have any edge in one image matching any edge in the other. The combinatorics of a naive matching strategy clearly could be enormous. A lot of the analysis of a matching strategy goes into bounding this combinatorics and constraining the search for edge correspondences.

One of the principal constraints used in stereo analysis may be determined from a knowledge of the relative attitudes of the cameras. If two equivalent cameras are arranged with axes parallel, as shown in Figure 5-1, then they can be conceived of as sharing a single common image plane. Any point in the scene will project to two points on that joint image plane (one through each of the two lens centers), the connection of which will produce a line parallel to the baseline between the cameras. Thus corresponding edges in the two images must lie along the same line in the

joint image plane. This line is termed an *epipolar line* (see [Hallert 1960], and section 4). If the baseline between the two cameras happens to be parallel to the scanning axis of the cameras, then the correspondence only need consider edges lying along matched lines parallel to that axis in the two images. These lines are termed *conjugate*. Figure 5-1 indicates this camera geometry — a geometry which produces *collinear epipolar lines*. The algorithm described here assumed the stereo pair to have such a geometry, and if this was not the case then the appropriate transformation of the two images had to be made before any processing could be done. A less restrictive solution would be to have the correspondence process informed of the camera geometries, and have it solve for the more general epipolar situation as shown in figure 5-2. Incorporation of this capability is one of the enhancements we have made to the system over the past few months. Section 4 details the analysis for this solution.

Specialized Epipolar Geometry  
Figure 5-1

General Epipolar geometry  
Figure 5-2

The advantage of processing along epipolar lines is that the search for correspondence may be constrained to one dimension, along a single line-pair. It is then feasible to apply an efficient optimization process to the matching problem. The Viterbi algorithm [Forney 1973] is the optimization process used in this system. It is a dynamic programming technique used extensively in speech processing, and first used in vision research in some recent work at Control Data Corporation [Henderson 1979]. An earlier use of a dynamic programming technique for stereo matching is documented in [Gimel'farb 1972]. [Baker 1981] describes in detail the use of the Viterbi algorithm for stereo correspondence.

Other geometric and photometric constraints may be introduced both in limiting search and in bounding parameters for the evaluation function. [Arnold 1980] and [Baker 1981] provide discussions of these constraints in determining edge correspondences.

### **5.3 Baker System: enhancements**

As stated, we undertook in this postdoctoral work to demonstrate the capabilities of the Baker system [Baker 1981] applied to some cultural scenes. Before carrying out these analyses we:

- a) enhanced the system with a capability to work with a better edge operator [Marimont 1982];
- b) enabled it to process images that are not graced with collinear epipolar geometry (*i.e.* most images);
- c) introduced an additional correspondence measure - edge extent.

To implement these enhancements required substantial redesign of the system, and redesign cycles with the Marimont process. Choosing useable data also presented difficulties, as the only imagery available was not of the correct geometry (see below). The two image pairs initially chosen (the Sacramento apartment complex and a section of some imagery of Moffett Field) proved, on closer examination, to require quite complex transformation, and could not be easily adjusted for epipolar processing. Obtaining useable data then tied the progress of this part of the demonstration to the progress of developing an image registration system.

In general, to bring imagery data into a properly transformed state could proceed in one of two ways:

- one could determine the transforms and then modify the imagery, producing an image pair having collinear epipolar geometry;
- or
- one could determine the transforms, and modify the output of an edge operator process that functions over the original imagery.

The latter is by far the superior approach, as it avoids resampling the image. This approach necessitates incorporating the transform computation into the stereo system, to follow edge finding and precede edge matching.

The second part of the stereo system's analysis is an intensity correlation process. This operates along epipolar lines as well, and clearly requires intensity information to be accessible along epipolar lines. One solution to this would be to take the original image pair and have the correlator rotate and change shape, size, and orientation as it moves around the image; this is an awkward and probably unnecessary complication. An alternative would be to access the transformed images, sampled as accurately as possible, and do the correlation in the rectangular space defined by collinear epipolar lines. The argument from edge accuracy indicated that transforming edges rather than resampling the image was the way to go; this argument from intensity correlation suggests that the resampled image can be useful.

Another implementation detail supported this use of both transformed edges and transformed imagery: it was found that the intensity information available from the Marimont process had too small a basis for useful correlation, and in fact, for transformed edges, had little relevance for the matching (it being measured not along epipolar lines). The transformed image had to be referenced again by the system to obtain more significant intensity estimates oriented along epipolar lines, and working with the image in epipolar space facilitated this.

The philosophy of the stereo matching process here had been to use edge analysis for, among other things, its higher accuracy, and to use intensity analysis for the continuity it provides. To be consistent with this, we wanted to have the highest possible accuracy for edges in epipolar space, and if sacrifice be needed for simplicity, to do it where it least degraded the analysis - in the intensity correlation. It is clear that transformed edges give higher accuracy than edges from transformed images (detectability might not change much, but localization is significantly reduced); and important simplifications could be obtained for little loss by doing the intensity correlation over the resampled image pair. This meant changes in our plans for the registration system: it had to produce not just transform information, but transformed images as well. Both forms are made available as output from the registration program described in section 4, and the enhanced Baker system uses them both. (However, the original edge finder of the stereo system has not been modified to use the transform information, and must work (at present) on the transformed images - with the limitations that brings.)

#### 5.4 The Marimont Edge Operator

The Marimont edge operator has greater detection and reliability than the original Baker edge operator, and similar localization; earlier examples of its processing convinced us that its output would improve the quality of our stereo reconstruction. Its ability to track along zero signal areas in following zero-crossing edges leads to more coherent image descriptions. [Marimont 1982] provides details of the operator's functioning. Roughly, it works by convolving an  $m \times m$  lateral inhibition function of  $n \times n$  central window with an image. Zero crossings in this resultant image then indicate edges, and the edge position is determined by interpolating over the lateral inhibition surface. Section 7 details the content and format of the edge files produced by this process.

A few unanticipated problems became apparent once work with the edges was begun. One point, noted above, was that the intensity information stored at an edge (its left and right boundary values) had quite small support (a single pixel). This is in contrast with the original operator which interpolated for these values in an area 3 pixels wide and removed one pixel from the determined edge position. Another problem was that the edge connectivity produced by the Marimont system can be misleading, as figure 5-3 shows. Intensity significance was improved by sampling along epipolar lines in the transformed images. The connectivity problem has not been looked at yet.

Good connectivity is inherently difficult to achieve with zero crossing operators. Refinements to the process are being considered.

Image  
Figure 5-3

The introduction of edge extent as a parameter in the dynamic programming solution was an obvious fallout from using the Marimont edges. Edges are output by that process as strings, with 2-connectedness. The maximum and minimum of some string, in transform space, is a measure of its (epipolar) extent. Prior to the use of this information the only way that global continuity entered the analysis was through a consistency enforcement relaxation process which ensured that edges connected in one view were interpreted as continuous in 3-space; all matching measures were quite local. With the modified approach, the correspondence measure is a function of (among other, more statistically based parameters) the ratio of edge extents. In particular, the likelihood of edge element  $a$  in the left image matching edge element  $b$  in the right image depends on the product of the ratios of the two upper extents (up from the edge elements) and the two lower extents (down from the two edge elements).

When image testing began with all of the above accomplished, another problem became apparent: the stereo system, bound into a machine architecture with a maximum of 256K words of memory, and always tightly wedged anyway, had grown with these changes to the point that only small portions of images could be worked on at once. Thus came to exist a windowing mechanism within the edge finding/loading and stereo matching processes.

### **5.5 Test Imagery**

Our testing has been progressing on several sets of imagery: a synthetic image pair from Control Data Corporation, an aerial scene from the Engineering Topographic Laboratory, and a building scene of Sacramento. The latter imagery is the most relevant to the current postdoctoral contract, and we will be demonstrating the mapping system on this data. This imagery may be seen in figures 4-6 and 4-8.

## 6: Bitpad Instructions

### 6.1 Instructions for the Digitizing Tablet

#### 6.1.1 - Introduction

The bitpad program is written in PASCAL to be run on a DEC KL-10 processor under WAITS at the Computer Science Department of Stanford University. It has an assembly code driver to handle input from the tablet over a normal RS-232 port (listing included also), and requires a graphics package available locally. Replacing this package for an intended use away from SAIL WAITS should be quite straightforward.

Locally, the bitpad may be run by typing DO TAB[S,HHB]. Figure 6 shows the digitizing tablet in use.

The initial preamble of questions deals with graphics options and line characteristics. You will usually want some sort of graphics output, so answer yes to the first question ("Want graphics output (y/n)?"). Graphics choices are DD or GOD (for later display). Say y to either or both of the questions about this. DD graphics go the Data Disc display while for viewing while you construct an edge file, while GOD graphics are for later Graphics Output Device device independent display. If you want little boxes drawn around the endpoints of lines, then answer y to ("Want boxes draw around vertices (y/n)?"). Box size refers to the size of the box to be drawn around vertices. Small is better for entry, large makes it easier to distinguish vertices from line nodes if you are trying to do deletions.

On the first digitizing pass over an image you will start directly from the bitpad; later sessions will involve adding to or editing an existing edge file. To enter an old file (or several old files), say Y to the question ("Want to read in a file (y/n)?"). This reads it in and displays it. For the moment there's a problem with reading strings into PASCAL, so it tries to read NEW.VRT[S,HHB]. If this file doesn't exist, it will give you the chance to enter another filename.. don't panic, just type in the new name.

When that file has been read in and displayed, it lets you choose another (ad infinitum). End with an answer of N (for NO) to the above question.

#### 6.1.2 - Setting screen coordinates

Whether you've read in a file, or not, you now set up the bitpad to enter data. It asks for the TTYline of the tablet (50 is the current line number of the bitpad plug). You then define the screen area on the bitpad: select the four corners with the crosshairs (lower left, upper left, upper right, lower right) with any button, and confirm your selection by pushing button '2' ('8' says no, try for four more points).

### **6.1.3 - Adding segments and vertices**

A 'segment' is made up of a start vertex, any number (even 0) of intermediate points, and an end vertex. Vertices may belong to any number of 'segments'. Adding vertices/points/segments is as follows:

Button: '1' defines a new vertex at the current crosshairs position, either starting a segment with it, or ending one there. '2' locates the nearest vertex (created by '1'), and begins or ends a segment there. '4' says add this point to the current segment list. '8' is a break. It lifts the pen. If it is followed by a '1' or '2', then that is all it does. If followed by a '4', it puts you in the delete cycle. If followed by another '8', you exit everything.

### **6.1.4 - Editing segments**

You may enter the editor to delete segments at any point. You do this by keying '8' then '4' in the above entry loop.

To delete segments, first choose a vertex attached to the segment with '1' button. Then select either the other vertex (if there is no ambiguity) with a '1', or a point somewhere on the segment with a '4'. You then see it erased on the screen, and you push '2' to confirm that that's the one you want deleted, or '8' to say that its not the one you want deleted. Leave the delete cycle by keying '8'.

If you wish to add more to the file, run it again, and this time read in the VRT file produced on this previous pass.

At the moment, the GOD file is the sum of everything drawn on the screen during the run. To get just the current description, you have to pass the file once more through the program; making no changes, just reading it in and writing it out. Because of this, I recommend NOT producing a GOD file on the 1<sup>st</sup> through  $n - 1$ <sup>st</sup> creation passes, saving it for the last run, when nothing will be altered.

*The Digitizing Tablet  
Figure 6-1*

## 7: Marimont Edge File Format

This section describes the format of the edge files created by the Marimont edge process.

### 7.1 Header

The file is binary, and begins with an 128-word header, followed by a list of linked edge lists (ledgels); that is, after the header, there are a number of items called ledgels, each of which is a list of edges.

The format of the header is as follows:

word	interpretation
0	unused; ignore
1	unused; ignore
2	bits per pixel in input picture
3	bias of laterally inhibited picture
4	"nil-strength" flag
5	"end-of-list" flag
6	first row of picture window
7	first col of picture window
8	last row of picture window
9	last col of picture window
10	1 if contours of positive regions, -1 if those of negative regions.
11	format number of edge file (format 3 currently);
12-127	unused; ignore

### 7.2 Ledgels

Next come one or more ledgels, followed by a word containing the end of list flag (word 5 of the header above). Each ledgel has a two word header, a list of one or more edges, and a word after the last edge containing the end of list flag. Note that this word flags the ends of two kinds of list: the list of ledgels, and the list of edges that each ledgel contains.

Each ledgel has the following format:

word	interpretation
0	1 if the ledgel is closed, i.e. the last edge is linked (conceptually) to the first, else 0.
1	number of left turns less the number of right turns in the ledgel, as one traverses the ledgel from head to tail.
2	beginning of this ledgel's list of edges

. [one or more edges]

last end-of-list flag

### 7.3 Edgels

Each ledgel has a list of one or more edges. There are two kinds of edges, corresponding to "significant" and "insignificant" zero crossings in the laterally inhibited image. A significant zero crossing is a transition of the laterally inhibited signal from positive to negative. An insignificant zero crossing is a transition of the laterally inhibited signal from positive or negative (depending on the sign of the region whose encircling contours are being detected, see word 10 of the header above) to zero, and as such does not correspond to a likely edge in the original image. Their exclusion from linked edge lists, however, seems to destroy much useful connectivity. So, we include them as "links" and assume that one between two significant zero crossings is not a significant break in the edge. But at insignificant zero crossings we do not estimate the strength of the edge or image intensities to either side as we do for significant zero crossings. Since less information is thus associated with insignificant zero crossings, we use two edge formats to save space.

The format for an edge is as follows:

word interpretation

- 0 interpolated row coordinate of edge point (floating-point)
- 1 interpolated column coordinate of edge point (floating-point)
- 2 integer equal to 0 if edge is horizontal, 1 if vertical
- 3 two possible interpretations: if when interpreted as an integer, it equals the nil-strength flag, then this is an insignificant edge point, the edge strength is undefined, and this is the last field in the edge. Otherwise, this edge is significant, this field should be interpreted as a floating-point estimate of the edge strength, and the next two words are fields belonging to this edge. all edge files as of this writing were created by encircling positive regions (see word 10 of the header), and in that case the edge strength is always positive, and the brighter side of the edge is towards the left as one moves from the head of the ledgel to the tail.
- 4 (significant edges only!) estimate of original image intensity to the left
- 5 (significant edges only!) estimate of original image intensity to the right

### 7.4 Clarifications

The edge location coordinates are in picture coordinates, i.e. with respect to the original picture, NOT w.r.t. the window in which they were detected. Integral locations correspond to pixel centers, not boundaries, and the topmost, leftmost pixel center is taken to be  $(0, 0)$ , which means that an  $m \times n$  picture has its upper left corner at  $(-0.5, -0.5)$ , and its lower right hand corner at  $(m - 0.5, n - 0.5)$  (since the indices of the last row, col are  $(m - 1, n - 1)$ ).

For the most part, edges are detected between horizontally or vertically adjacent pixels, which is why there are only two possible orientations for edges. An edge is detected between two such adjacent pixels if the laterally inhibited signal is positive at one and negative at the other. The edge location is estimated by the linearly interpolated zero crossing between these two values. Edge strength is the difference between laterally inhibited intensities one pixel to either side of estimated zero crossing (in the directions normal to that of the zero crossing); linear interpolation is used to estimate each of these intensities, since the points at which they're measured usually fall between pixels. The strength is scaled down to correspond to the difference between adjacent pixels (i.e. the strength measure is laterally inhibited contrast per pixel unit measure). Image intensities are estimated at these same points, i.e. one pixel to either side of the interpolated zero crossing, in an analogous way, by linearly interpolating between each pair of image intensities. However, both image intensities are retained.

The reason for the "for the most part" in the first line of the paragraph above is that "extended" zero crossings are detected in the current implementation. An extended zero crossing is three adjoining pixels in a row or column with one end pixel positive, one end pixel negative, and the middle pixel zero (values refer to the laterally inhibited signal). The estimates of edge location and strength and left and right image intensities are made just as in the above: the location of the edge is an interpolated zero-crossing, the edge strength is the (scaled) difference in (interpolated) laterally inhibited pixel values one pixel to either side of the estimated location, and the left and right image intensities are interpolated image intensities one pixel to either side of the estimated location.

## 8: Conclusions

### 8.1 Summary

A principal research interest of our group is in developing a rule-based advanced automated stereo mapping system to function within ACRONYM [Brooks 1981]. Current mapping techniques ignore much of the information available from inference on single views of a scene. This information can be useful for three-dimensional surface interpretation, and also provides extra parameters for stereo matching (i.e. surface orientation, occlusion cues). Our research effort is directed at establishing such monocular inference rules in a rule-base for stereo mapping.

In deriving these rules, we perform analysis of both hand extracted and automatically produced edge descriptions. A facility has been developed under the current postdoctoral contract for this manual edge extraction from hardcopy imagery. We have studied rule synthesis for several cases, including that of orthogonal trihedral vertices - features that dominate cultural scenes. This research is very promising, and has shown the utility of the rule-based approach to surface inference from monocular information. We will be continuing our research in rule synthesis under other funding.

Camera solving provides powerful constraint on the correspondence problem in stereo matching. We have developed a facility under this contract for interactively registering images, determining the parameters for transforming them (or their edge descriptions) into collinear epipolar space, and performing the actual image transformation. This determination is crucial to a mapping process. Incorporating an automated module to provide data for the camera solving is a very important next step.

We have experimented with an existing stereo mapping process, enhancing its flexibility with respect to image format and with respect to edge operator format, and have been preparing example outputs of its processing on new imagery. Our intent with this effort has been to show the capabilities of a local matching process and to assess its applicability to the planned rule-based system.

### 8.2 Demonstration

We will be demonstrating the following for RADC later in May:

- a) an interactive digitizing test facility;
- b) the use of image edge descriptions produced using this facility and from an automated process [Marimont 1982] in synthesizing rules for stereo matching;
- c) examination of Orthogonal Trihedral Vertex (OTV) inference rules;

- d) development of a system for registration of image pairs;
- e) analysis of stereo imagery with an automated stereo process.

Our demonstration will also present related equipment and system facilities that we use in support of this and other vision research.

## 9: Digitizing Program

end "PARAMETERS";

$\alpha$  Geometric procedures;

SIMPLE PROCEDURE RECT(REAL EX,EY,VX,VY,RO;REFERENCE REAL X,Y);

$\alpha$  rect returns the rectangular coordinates of a point with polar coordinates ro and  $\alpha$  with respect to a shifted origin e(ex,ey).  
 vx and vy are supposed proportional to  $\cos \alpha$  and  $\sin \alpha$ , but vx>0:  
 $\alpha$  is always in  $[-\pi/2, \pi/2]$ , and RO should have a sign;

```
BEGIN "RECT"
  X=SQRT(VX*2+VY*2);
  VX=VX/X;
  VY=VY/X;
  X=EX+RO*VX;
  Y=EY+RO*VY;
END "RECT";
```

PROCEDURE POLAR( REAL EX,EY,X,Y; REFERENCE REAL THETA,RO);

$\alpha$  POLAR returns the polar coordinates of a point (x,y) with respect to a shifted origin (ex,ey)  
 RO is always a positive number, and THETA is in the determination  $[0, 2\pi]$ ;

```
Begin "POLAR"
  RO=SQRT((EX-X)*2+(EY-Y)*2);
  THETA=ATAN((EY-Y)/(EX-X));
  IF (X-EX)<0 THEN THETA=THETA+ $\pi$ ;
  IF THETA < 0 THEN THETA=THETA+2* $\pi$ ;
END "POLAR";
```

```

SIMPLE PROCEDURE NEWX( REAL EX,EY,VX,VY;REFERENCE REAL NX);
  α A point E has the coordinates EX and EY in a plane where there is a vector V.
  If this plane is rotated so that V becomes the new X-axis, and shifted so
  that the old origin is anywhere on the new Y-axis, the new abscissa of
  E is just its projection onto V::
  BEGIN: NX←(EX*VX+EY*VY)/SQRT(VX*2+VY*2);END;

```

```

BOOLEAN PROCEDURE INPICTURE(REAL X,Y,LX,LY);
  RETURN( IF (0≤X≤LX ∧ 0≤Y≤LY) THEN TRUE ELSE FALSE);

```

```

PROCEDURE LIMITS( REAL LX,LY,EX,EY;REFERENCE REAL ALPHA0,ALPHA1,DMIN,DMAX;
  REFERENCE BOOLEAN RIGHT);

```

```

  α LIMITS returns:
  1) the minimum and maximum distances DMIN and DMAX from a point
  E to a rectangle of length LX and height LY with bottom left corner at
  origin. ( typically, a picture and its epipole )
  2) The minimum and maximum angle through which the rectangle is viewed
  from point E. These angles ALPHA0 and ALPHA1 are in the determination
  [0,2π] ( or occasionally, [-π/2,π/2] ) and the distances are consequently
  positive only.;

```

```

  BEGIN "LIMITS"
    REAL X,Y;
